Abstract—Composition is amongst the major challenges faced in language engineering. Erdweg et al. offered a taxonomy for language composition. Mernik catalogued the use of the Language Definitional Framework LISA for composition sorts in that taxonomy. We produce a similar catalogue for embedded language engineering in Scala.

We begin with techniques that are not specific to Scala. They are applicable in any host language with a module system and support for higher order functions. We, then, present two more techniques to examine Scala-specific language engineering. Interestingly enough, even though dealing with embedded languages, in terms of lines of code, our material is of comparable length to its LISA counterpart. Our work lends insight into Scala’s serviceability for composition, as a host for embedded language engineering.

I. INTRODUCTION

a) Language composition is a piece of reality!: Everyday, there are new programming languages that are born by combining ideas from older languages. Inspiration aside, that is an act of composition in many cases. For example, roughly put, Scala adds functional programming and ML modules with mixin composition to Java; which, in return, is C++ without pointers; which, in return, is C with OOP.

The taxonomy of Erdweg et al. [1] suggests a terminology and notations for describing such compositions. According to them, one can formalise our Scala description as:

$$\text{Scala} \approx \text{C} \triangleleft \text{C++} \triangleright \text{Java} \triangleleft (\text{MLModule} \uplus \text{Mixin}) \quad (1)$$

b) Observations from Chemistry: Consider the reaction:

In Chemistry, two key ingredients for success in the study of such equations are: (CI₁) the availability of substances as the *subjects of study*, and, (CI₂) knowledge about *how* to perform a desirable composition. In reaction (2), for instance, both substances H_2SO_3 and NaOH need to be available. One also needs to know how to double NaOH for the equation balance to be right. Also, how to add NaOH to H_2SO_3 (like the rate of addition, proper temperature, etc.) needs to be known.

c) Programmatic Availability & Composition: The study of formulae like equation (1) determines the precise relative position of languages. Using the outcome, one would be able to add, for example, what is missing in equation (1) so that the “ \approx ” can be replaced by an “ $=$ ”. One would also gather that the left-out “FP \uplus ” is necessary right before MLModule for the balance to be right. Such manipulations are similar

to adjusting coefficients in reaction (2) to obtain a balance. Similar to Chemistry, two key ingredients become noticeable here: (PLI₁) *programmatic* availability of programming languages themselves and their belongings as the subjects of study, and, (PLI₂) knowledge about how to *programmatically* obtain desirable language compositions.

By the time of this writing, (mainstream) languages are next to inaccessible as programmatic entities. The study of programmatic language composition, nonetheless, can be conducted independently using, say, contrived languages. That is how this paper tries to gain (PLI₂).

d) Contributions: We demonstrate three techniques for composing languages embedded in Scala. The first (Section II) is applicable in any host language with a module system and support for higher order functions. The second (Section III) is based on Lightweight Modular Staging (LMS) [2]. And, the third – which is also a new solution to the Expression Problem (EP) [3], [4], [5] – employs (possibly restricted) abstract types. The trick in our third technique is promoting the cases of Algebraic Data Types (ADTs) into their own ADT-parameterised standalone components. We showcase each technique using the example compositions of Mernik [6]. We, then, compare the three techniques for their success in addressing the EP concerns (Section V). A discussion about the related work also comes at Section VI.

e) Coding Conventions: This paper assumes familiarity with Scala. For each showcase, the syntax and semantics come in separate packings called `syntax` and `semantics`, respectively. Due to space restrictions, in our code, the name of the showcase is only appended as a comment to the end of the first line of the respective `syntax` or `semantics`. For the same reason, our code is also otherwise unusually compressed. Whilst the showcases are referred to in the prose in CamlCase, their respective Scala package (containing the showcase’s `syntax` and `semantics`) is named `like_this` or abbreviated as `lt`.

II. SCALA-UNSPECIFIC

Erdweg et al. catalogue five different ways languages can be composed: language extension, language restriction, language unification, self-extension, and extension composition. Mernik offers simple DSLs to showcase those ways in LISA [7]. In this section, we employ Mernik’s simple DSLs for the same purpose, albeit in Scala.

A. Language Extension

A base language B is said to be extended to a language E when the description of B is amended with a description fragment to get E . Erdweg et al. denote that by $B \triangleleft E$. Consider the language Robot below (packaged under the name robot in Scala) for a robot arm that takes commands for moving one unit to either of the four 2D directions. The semantics of Robot involves updating the arm's position (recorded in terms of the x and y coordinates) based on the commands (lines 11 to 16).

```
1 object syntax { //robot
2   class Command
3   case object Left extends Command
4   case object Right extends Command
5   case object Up extends Command
6   case object Down extends Command
7   case class Commands(s: Seq[Command])
8   object semantics { import syntax._ //robot
9   class Position(var x: Int, var y: Int)
10  object position extends Position(0, 0)
11  def locate: Command => Unit = {
12    case Left => position.x -= 1
13    case Right => position.x += 1
14    case Up => position.y += 1
15    case Down => position.y -= 1
16  }
17  def locate(cs: Commands) = cs.s.foreach(locate)
18 }
```

Robot is extended to RobotTime (the robot_time package) by adding to the semantics, i.e., $\text{Robot} \triangleleft \text{RobotTime}$:

```
1 package robot_time
2 import robot._; import syntax._
3 def time(cs: Commands): Int = cs.s.length
```

Assuming that executing each command takes one time unit, the total time required for a set of commands is the size of the set. The method time in line 3 above adds that piece of semantics to Robot to get RobotTime. whereas Commands(Right, Down, Down) in Robot has only got the semantics $x = 1, y = -2$, it also has the semantics $t = 3$ in RobotTime. (The coordinates are obtained by locate in line 16 of robot and the timing by line 3 of robot_time.)

Here is a difference between our implementation of RobotTime and that of Mernik: The latter is done in LISA: a Language Definitional Framework (LDF) that combines OOP with Attribute Grammars (AGs) [8], [9]. As such, LISA's counterpart for time has to visit all the grammatical rules in Robot to attribute the new piece of semantics to them. On the contrary, Scala gave us the joy of simply equating time by the number of the commands, regardless of the grammatical rules involved.

B. Language Restriction

A base language B is said to be restricted to a language R when certain parts of the B 's features are removed upon transition to R . This is denoted by $B \triangleright R$. A typical usage of that is when a language is narrowed to a core of it. That is, certain parts of the base syntax are cancelled into combinations of other base syntactic parts that are deemed to be equivalent. For example, both GPH [10] and Utrecht HASKELL [11] are developed like that.

The language RobotPositive below (packaged under robot_positive) restricts Robot to only Up and Right commands. (Technically, the object syntax below is not required. Yet, we retain it for completeness.)

```
1 object syntax { //robot_positive
2   import robot.syntax.{Right, Up, Commands}
3   object semantics { //robot_positive
4   import robot.syntax.{Right, Up, Commands}
5   import robot.semantics.position
6   def locate(cs: Commands) {
7     for(c <- cs.s) c match {
8       case Right => position.x += 1
9       case Up => position.y += 1
10    }
11  }
12 }
```

Any attempt to use the expression in the previous section under RobotPositive will fail to compile for the availability of Down in it, which is absent in RobotPositive. On the other hand, Commands(Right, Up, Up) has the semantics $x = 1, y = 2$ under RobotPositive.

C. Language Unification

Erdweg et al. say two languages L_1 and L_2 are unified to L when both L_1 and L_2 make sense independently from one another and from L (as the composition's outcome). Furthermore, in L , neither L_1 nor L_2 should be dominated by the other so that a concept of equity prevails in the composition. The notation is $L = L_1 \uplus_g L_2$, where g is the so-called glue code required for the composition.

Having seen the language Robot, we now consider the language ExprAdd (packaged under expr_add): a simple ADT with two cases for natural numbers and addition.

```
1 object syntax { //expr_add
2   class Expr { //Expr ::= Expr + Term | ...
3     def + (t: Term): Expr = Add(this, t)
4   }
5   class Term extends Expr { //Expr ::= ... | Term
6     //Term ::= n
7     case class Num(n: Int) extends Term
8   }
9   case class Add(left: Expr,
10    right: Term) extends Expr
11 }
12 object semantics { //expr_add
13   import syntax._
14
15   def value: Expr => Int = {
16     case Num(n) => n
17     case Add(e, t) => value(e) + value(t)
18   }
19 }
```

Using value in line 15 above, one obtains the semantics 5, 12, and 6 for the expressions Num(5), Num(10) + Num(2), and Num(1) + Num(2) + Num(3), respectively.

The language RobotUniExprAdd below (packaged under robot_uni_expr_add) unifies Robot and ExprAdd by allowing the robot arm to take commands for moving as many units to either of the four directions as the corresponding ExprAdd argument evaluates to. As such, Commands(Right(Num(5)), Up(Num(2) + Num(10)), Up(Num(2) + Num(2) + Num(2)), Down(Num(4))) has the semantics $x = 5, y = 14$. Check locate in line 17 below.

```
1 object syntax { //robot_uni_expr_add
```

```

2 import robot.syntax.Command
3 import expr_add.syntax._
4
5 case class Left(e: Expr) extends Command
6 case class Right(e: Expr) extends Command
7 case class Up(e: Expr) extends Command
8 case class Down(e: Expr) extends Command
9
10 object semantics { //robot_uni_expr_add
11 import robot.syntax.Commands
12 import robot_uni_expr_add.syntax._
13
14 import robot.semantics.position
15 import expr_add.semantics._
16
17 def locate(cs: Commands) {
18   for(c <- cs.s) c match {
19     case Left(e) => position.x -= value(e)
20     case Right(e) => position.x += value(e)
21     case Up(e) => position.y += value(e)
22     case Down(e) => position.y -= value(e)
23   }
24 }
25 }

```

D. Self Extension

This is the situation when the description of a language L itself is used for extending it. Typically, embedded DSLs self-extend their host language. For example, all the languages we present in this paper self-extend Scala.

Like Mernik, we believe that demonstrating self extension takes much more than the volume of a single research paper. This is because bootstrapping a language L to the level where it can handle self extension is already more involved than that volume. Hence, we too drop demonstration of self extension.

E. Extension Composition

Extension composition is when (both or at least one of) the language descriptions that are to be composed are themselves compositions of other language descriptions. As such, extension composition can be regarded as higher order composition. Six combinations of extension and unification are possible (three distinguished by Mernik):

- 1) Double-Unification (\uplus): $L_1 \uplus_g (L_2 \uplus_h L_3)$.
- 2) Double-Extension (\triangleleft): $B \triangleleft E_1 \triangleleft E_2$.
- 3) Extension by a Unification ($\triangleleft (\uplus)$): $B \triangleleft (L_1 \uplus L_2)$.
- 4) Extension of a Unification ($(\uplus) \triangleleft$): $(L_1 \uplus L_2) \triangleleft E$.
- 5) Unification with an Extension ($\{\uplus, \triangleleft\}$): $L \uplus (B \triangleleft E)$ or $(B \triangleleft E) \uplus L$. Note the symmetry.

We now consider each combination.

1) *Double-Unification* (\uplus): To that end, we begin by presenting Mernik's language Dec (packaged under dec) in Scala. Dec enables the programmer to bind a set of variables to integer constants.

```

1 object syntax { //dec
2   case class ConstDefList(ds: Map[String, Int]) }

```

Unsurprisingly, the (Scala-automatic) semantics of ConstDefList("a" -> 5, "b" -> 10) is then $\{a \mapsto 5, b \mapsto 10\}$.

With that, we illustrate the first class of Mernik's extension compositions using RobotUniExprAddUniDec (packaged under rueaud). As suggested by its name, this language is (Robot \uplus ExprAdd) \uplus Dec. The Robot \uplus ExprAdd portion is already presented. See robot_uni_expr_add in Section II-C. We now show how to obtain the remaining unification.

```

1 import expr_add.syntax.{Expr, Term}
2 object syntax { //rueaud
3   import robot.syntax.Commands; import dec.syntax._
4   implicit class CDLInCs(val cdl: ConstDefList) {
5     def in (s: Commands) = {
6       consts = cdl.ds; new EnvComm(cdl.ds, s)
7     }
8   }
9   class EnvComm(val ds: Map[String, Int],
10                 val cs: Commands)
11   var consts: Map[String, Int] = Map()
12   case class Var(n: String) extends Term
13 object semantics { //rueaud
14   import syntax._; import robot_uni_expr_add.syntax._
15   import robot.semantics._
16   def value_ext: (Expr, Expr => Int) => Int = {
17     case (Var(n), c) => consts(n)
18     case (e, c) =>
19       expr_add.ext_semantics.value_ext(e, c)
20   }
21   def value(e: Expr): Int = value_ext(e, value)
22   def locate(r: EnvComm) {
23     r.cs.s.foreach {
24       case Left(e) => position.x -= value(e)
25       case Right(e) => position.x += value(e)
26       case Up(e) => position.y += value(e)
27       case Down(e) => position.y -= value(e)
28     }
29   }
30 }

```

rueaud.syntax aims at reusing the former language descriptions as they are. To that end, it takes a *pimp my library* approach [12] on trying to implicitly (lines 4 to 10 above) give instances of dec.ConstDefList the extra feature of being followed by commands possibly referring to the declarations. Such declarations followed by expressions are then instances of EnvComm. The variable consts (line 11) is where the processed declarations are stored. The new ADT case Var (line 12) is for looking up the value a name is bound to. rueaud legitimises commands for moving the robot arm as many units as a pertaining expression evaluates to (lines 23 to 26). Note that, because of Var, those expressions can refer to declarations as well. All that together gives ConstDefList("a" -> 5, "b" -> 10) in Commands(Right(Var("a")), Up(Num(2) + Var("b")), Down(Num(4))) the semantics $x = 5, y = 8$ in RobotUniExprAddUniDec.

Instead of reusing expr_add.semantics.value, the rueaud.semantics.value method uses the method expr_add.ext_semantics.value_ext, which will be explained shortly. This is because the former is closed on the set of ADT cases it can handle. Hence, we resort to the following *extensible* semantics of ExprAdd:

```

1 object ext_semantics {
2   import syntax._
3   def value_ext: (Expr, Expr => Int) => Int = {
4     case (Num(n), c) => n
5     case (Add(e, t), c) => c(e) + c(t)
6   }
7   def value(e: Expr): Int = value_ext(e, value)
8 }

```

In the fashion of $\gamma\Phi C_0$ [13], value_ext above takes a continuation argument c (line 3), which caters postponing the closing time until the appropriately complete shape [14] of the ADT is known (line 6 above for expr_add and line 20 for rueaud). As such, extending RobotUniExprAdd to RobotUniExprAddUniDec here involves manipulating the former. See Section V for more.

2) *Double-Extension* (\triangleleft): The idea in RobotTimeSpeed below (packaged under robot_time_speed) is to enable

the user to instruct the robot arm with the speed for its subsequent moves, until further notice. It adds a pertaining command to RobotTime to obtain Robot \triangleleft RobotTime \triangleleft RobotTimeSpeed.

```

1 object syntax { //robot_time_speed
2   import robot.syntax.Command
3   case class Speed(i: Int) extends Command
4 }
5 object semantics { //robot_time_speed
6   import syntax._; import robot.syntax.{Command, Commands}
7   import robot.semantics.position
8   def locate: Command => Unit = {
9     case Speed(_) => {}
10    case c => robot.semantics.locate(c)
11  }
12  def locate(cs: Commands) = cs.s.foreach(locate)
13  var speed: Double = 1.0
14  def time(cs: Commands): Double = {
15    var sum: Double = 0.0
16    for(c <- cs.s) c match {
17      case Speed(i) => speed = i
18      case _ => sum += (1.0 / speed)
19    }
20    sum
21  }

```

The new command for altering speed is Speed in line 3 above. This new command has no impact on the arm's position, as manifested in line 9. It is in the time calculation where, once used, the related variable (i.e., speed in line 12) is updated accordingly (line 16) and taken into consideration for subsequent commands (line 17). Commands(Up, Speed(2), Right, Left) has the semantics $x = 1, y = 0, t = 2$ in RobotTimeSpeed.

3) *Extension by a Unification (\triangleleft (\oplus))*: We now demonstrate RobotExtExprAddUniDec = Robot \triangleleft (ExprAdd \oplus Dec). We begin by ExprAddUniDec (packaged under eaud):

```

1 import expr_add.syntax._
2 object syntax { //eaud
3   import dec.syntax._
4   class EnvExpr(val ds: Map[String, Int], val e: Expr)
5   implicit class CDL2CDLInE(val cdl: ConstDefList) {
6     def in (e: Expr) = {
7       consts = cdl.ds
8       new EnvExpr(cdl.ds, e)
9     }
10  }
11  var consts: Map[String, Int] = Map()
12  case class Var(n: String) extends Term
13 }
14 object semantics { //eaud
15   import syntax._
16   import dec.syntax._
17   def value_ext: (Expr, Expr => Int) => Int = {
18     case (Var(n), c) => consts(n)
19     case (e, c) => expr_add.ext_semantics.value_ext(e, c)
20  }
21  def value(e: Expr): Int = value_ext(e, value)
22  def value(ee: EnvExpr): Int = value(ee.e)
23 }

```

eaud is similar to rueaud in Section II-E1 and we drop further explanation. RobotExtExprAddUniDec below (packaged under reeaud) tries to make use of eaud.

```

1 object syntax { //reeaud
2   import dec.syntax._; import robot.syntax.Commands
3   class EnvComm(val ds: Map[String, Int], val cs: Commands)
4   implicit class CDL2CDLInC(val cdl: ConstDefList) {
5     def in (s: Commands) = {
6       consts = cdl.ds
7       new EnvComm(cdl.ds, s)
8     }
9   }

```

```

10 }
11 var consts = eaud.syntax.consts
12 }
13 object semantics { //reeaud
14   import robot.semantics.position
15   import robot.uni_expr_add.syntax._
16   import eaud.semantics.value; import syntax._
17   def locate(r: EnvComm) {
18     r.cs.s.foreach {
19       case Left(e) => position.x -= value(e)
20       case Right(e) => position.x += value(e)
21       case Up(e) => position.y += value(e)
22       case Down(e) => position.y -= value(e)
23     }
24   }
25 }

```

Here are the few idiosyncrasies of reeaud: Firstly, reeaud fails to reuse most of the syntactic facilities of eaud. This is because the former employs declarations followed by commands, whereas the latter employs declarations followed by expressions. In line 11, nevertheless, consts is reused. Secondly, even though RobotExtExprAddUniDec = Robot \triangleleft ..., in reeaud.semantics, we do not reuse robot.syntax. On the contrary, in line 15, it reuses the syntax of robot_uni_expr_add (for RobotUniExprAdd). This is because, in Robot, it is only possible to move the arm one unit to either direction. The Scala syntax for those two pieces of (embedded) syntax cannot coexist side by side. See Section III-A2 for more.

reeaud.semantics.locate is similar to rueaud.semantics.locate. In RobotExtExprAddUniDec, ConstDefList("a" -> 5, "b" -> 10) in Commands(Right(Var("a")), Up(Num(2) + Var("b")), Down(Num(4))) has semantics $x = 5, y = 8$.

As pointed out by Mernik, so long as functionality is the only concern, RobotUniExprAddUniDec \equiv RobotExtExprAddUniDec. The difference, both in LISA and Scala, is in the language descriptions, and the combinations by which they are obtained. Unlike its LISA counterpart, nonetheless, obtaining RobotExtExprAddUniDec in Scala involves intermediate material that is not reused in the final product.

4) *Extension of a Unification (\triangleleft (\oplus))*: RobotUniExprAddExtRobotTime below (packaged under rueaert) extends RobotUniExprAdd (Section II) by a timing facility. The time required for carrying out a command of moving in one direction equals what the pertaining expression evaluates to (lines 9 to 12). The method time below is a simple fold operation on the given sequence of commands, based on that explanation. RobotUniExprAddExtRobotTime = (Robot \oplus ExprAdd) \triangleleft RobotTime.

```

1 object syntax { //rueaert
2   import robot_uni_expr_add.syntax._
3 }
4 object semantics { //rueaert
5   import expr_add.semantics._
6   import robot.syntax.Commands
7   import robot_uni_expr_add.syntax._
8   def time(cs: Commands): Int = (0 /: cs.s) {
9     case (s, Left(e)) => s + value(e)
10    case (s, Right(e)) => s + value(e)
11    case (s, Up(e)) => s + value(e)
12    case (s, Down(e)) => s + value(e)
13  }
14 }

```

Commands(Right(Num(5)), Up(Num(2) + Num(10)),
Up(Num(2) + Num(2) + Num(2)), Down(Num(4))) has
the semantics $x = 5, y = 14, t = 27$ in rueaert.

5) *Unification with an Extension* ($\{\oplus, \triangleleft\}$):
Take RobotUniExprMul = Robot \oplus ExprMul, where
ExprAdd \triangleleft ExprMul. The language ExprMul extends
ExprAdd by a new ADT case for multiplication (Mul).
What is unique about ExprMul amongst the visited extension
combinations is that, upon extension, it changes the syntactic
categories of the ADT cases it borrows from ExprAdd.
(And, in fact, it also provides a new syntactic category, i.e.,
Factor.) As presented in Section III-B, this can impose
a great deal of complexity when language extension is
implemented using inheritance. Here is ExprMul (packaged
under expr_mul).

```
1 import expr_add.syntax.{Expr, Term, Add}
2 object syntax { //expr_mul
3   //Term ::= Factor | ...
4   class Factor extends Term
5   implicit class TermTimesFactor(val t: Term) {
6     def * (f: Factor): Term = Mul(t, f)
7   } //Term ::= ... | Term * Factor
8   //Factor ::= n
9   case class Num(n: Int) extends Factor
10  case class Mul(left: Term,
11                right: Factor) extends Term
12 }
13 object semantics { //expr_mul
14   import syntax._
15   import expr_add.
16   ext_semantics.{value_ext => add_value}
17
18   def value_ext: (Expr, Expr => Int) => Int = {
19     case (Num(n), c) => n
20     case (Add(e, t), c) =>
21       add_value(Add(e, t), c)
22     case (Mul(t, f), c) => c(t) * c(f)
23   }
24   def value(e: Expr): Int = value_ext(e, value)
25 }
```

In line 1, ExprMul imports the syntactic entities it borrows
from ExprAdd: the ADT case Add and the syntactic categories
Expr and Term. It then introduces its new syntactic category
Factor in line 4. Next, in lines 5 to 7, it provides the syntactic
sugar for multiplication. Note how it, afterwards, declares
numbers to now be of the category Factor – as opposed to
Term in expr_add.syntax. The rest of expr_mul should
be straightforward except for the Scala syntax of lines 15
to 16. Those lines abbreviate expr_add.ext_semantics.
value_ext to add_value in expr_mul.semantics. In
line 21, expr_mul reuses add_value for the solo ADT case
that it borrows from expr_add, i.e., Add.

```
1 object syntax { //robot_uni_expr_mul
2   import robot.syntax.Command
3   import expr_add.syntax.Expr
4   import expr_mul.syntax._
5
6   case class Left(e: Expr) extends Command
7   case class Right(e: Expr) extends Command
8   case class Up(e: Expr) extends Command
9   case class Down(e: Expr) extends Command
10 }
11 object semantics { //robot_uni_expr_mul
12   import robot.syntax.Commands
13   import syntax._
14
15   import robot.semantics.position
16   import expr_mul.semantics._
```

```
17 def locate(cs: Commands) = cs.s.foreach {
18   case Left(e) => position.x -= value(e)
19   case Right(e) => position.x += value(e)
20   case Up(e) => position.y += value(e)
21   case Down(e) => position.y -= value(e)
22 }
23 }
24 }
```

The above implementation of RobotUniExprMul (packaged
under robot_uni_expr_mul) takes tightly after RobotUni-
ExprAdd (in Section II-C). We, therefore, do not provide
a dedicated walk-through. Commands(Right(Num(5) * Num
(2)), Down(Num(4) + Num(2) * Num(3))) has the seman-
tics $x = 10, y = -10$ in robot_uni_expr_mul.

F. Language Specific?

To investigate the extent to which Scala-specific language
features impact upon our design, we intend also to com-
pare against realisations in other languages. To this end, we
have prepared a C++ implementation which adopts the Scala
approach outlined so far. Respecting the dynamic polymor-
phism of the Scala original, the C++ implementation utilises
shared_ptr smart pointer to manage the memory allocation
and runtime typing of expressions; allowing the vector
container member object of the Commands class to store
different expression types. User-defined integral and string
literals also allow a notably concise syntax for the Num and Var
instantiations; e.g., Commands{Right{"a"_s}, Up{2_n +
"b"_s}, Down{4_n}}. Future work will explore this further.

Note that we are keen in the solution of this section not
to employ Scala's built-in open recursion. Due to unrelated
reasons, however, Scala compilers might still employ open
recursion internally to compile our code. Nonetheless, our
code does not require that Scala idiosyncrasy. Testimony to
that lack of requirement is our C++ code. Note that whilst
open recursion is automatic in Scala, in C++, one needs to
explicitly use "this->" for the late-binding of open recursion.

III. LMS-BASED

Rompf and Odersky [2] coin Lightweight Modular Staging
(LMS) for Polymorphic Embedding [15] of DSLs in Scala.
They employ a fruitful combination of the Scala features
detailed in [16] that, as a side-product, offers a very simple
yet effective solution to EP. In this paper, we use LMS for
that EP solution. The essence of LMS is the use of Scala
traits for extensibility and **super** calls for reuse. With their
mixin nature, Scala traits can extend one another, enjoying the
benefits of inheritance. In particular, an ADT can be inherited
upon trait extension. But, the heir trait can also add its own
new ADT cases. On top of that, **super** calls enable reusing
methods on the cases of the original ADT. Whereas the new
cases can be handled by the same method, albeit overridden
by the heir trait.

In the package eaud below (for ExprAddUniDec), for
implementing both the syntax and semantics, traits are used
– as opposed to objects in Section II. Instead of **importing**
members from other languages, it now **extends** those other
languages to acquire the same members via inheritance. In

Scala terms, `eaud.syntax` is, for instance, said to be mixing in `expr_add.syntax` and `dec.syntax`, in line 1 below.

In line 4, then, `eaud.semantics` overrides `value`. In line 5, it handles the new ADT case `eaud.syntax` introduces. All those other ADT cases that `eaud` inherits are, in line 6, relayed to the upper levels of inheritance.

```
1 trait syntax extends expr_add.syntax with dec.syntax {
2   ... /* like eaud.syntax in Section II-E3 */ ...
3 trait semantics extends syntax with expr_add.semantics {
4   override def value: Expr => Int = {
5     case Var(n) => consts(n)
6     case e      => super.value(e) } ...}
```

This is how LMS facilitates both simplicity and extensibility. (Note that we needed not to resort to `value_ext`.)

LMS has been successfully employed for languages in a multitude of applications. For the benefits of LMS, the reader is invited to consult those works. Given that we did not come to observe new benefits, we will not get into that here. We rather dedicate this section to the difficulties we faced over employing LMS for embedded language composition.

A. Minor Difficulties

The two categories of minor difficulties we faced relate to language restriction (Section III-A1) and clashes occurred between names upon composition (Section III-A2).

1) *Language Restriction*: Upon extension, the programmer is usually provided with no means for acting selectively on the members to be inherited. When mixing traits too, all the (public or protected) members get inherited automatically. Hence, with inheritance being the means for language composition, language restriction is not possible. That enforces `import` as the fallback. With the use of traits, the mechanics is, however, more involved than Section II. Because traits are abstract, one needs to materialise them first (line 2 below), and only then, they can be `imported` from (line 3).

```
1 trait syntax/* robot_positive */{
2   val robosyn = new robot.syntax {}
3   import robosyn.{Right, Up, Command, Commands}
4 }
```

Even though LISA also employs inheritance for language composition, this difficulty does not arise there. The reason is as follows: Being also an AG system, (subject) language semantics is specified in LISA by traversing the concrete syntax. On the other hand, leveraging its OOP, LISA allows the heir language to override the parent language’s concrete syntax. As a result, language restriction is also possible in LISA via inheritance.

One final related comment: In our experience, enforced `imports` like those required for language restriction were not exclusive to that way of language composition. In fact, in a good number of other occasions, the languages do make selective use of one another. That, on its own, was not a knotty problem. It, however, requires increasingly more care when it comes to interplay with hierarchies of languages and the relevant Scala mixins.

Note that `imported` names (like those in line 3 above) do not get inherited but the respective materialised traits

(like `robosyn` in line 2 above) do. Such `imports` can be required on several occasions down the hierarchy. In the case of unification, however, where the multiple inheritance nature of mixins is employed, an extra `override` might also be enforced to disambiguate duplicated names across the meeting two hierarchies. See Section III-B for more.

2) *Name Clash*: Recall from Section II-E3 that `RobotExtExprAddUniDec = Robot < (ExprAdd \uplus Dec)`. In an LMS-based implementation of `RobotExtExprAddUniDec`, therefore, one would naturally want to implement `rueaud.semantics` as follows:

```
1 trait semantics extends rueaud.syntax with
2   robot.semantics with eaud.semantics {//rueaud
3   ... /* locate like Section II-E1 */ ...}
```

That is, however, not possible. The error message is: “object Left is not a case class, nor does it have an `unapply` /`unapplySeq` member.” The problem is that, even though `Left` is inherited from `robot`, in `locate`, Scala would not be able to match it using the syntax `Left(e)`. The available constructor and extractor of `Left` take no arguments. Moreover, overloading that syntax is not possible. This is because Scala desugars both case classes and case objects to objects with `unapply` (or `unapplySeq`) methods. Objects, on the other hand, are final, banning any later manipulation. To proceed, one needs to use `robot_uni_expr_add.semantics` in return of `robot.semantics`.

The problem is harder to diagnose for `RobotUniExprAddExtRobotTime`. Recall from Section II-E4 that `RobotUniExprAddExtRobotTime = (Robot \uplus ExprAdd) < RobotTime`. For the attempt

```
1 trait semantics extends rueaert.syntax with
2   robot_uni_expr_add.semantics with
3   robot_time.semantics {... /* rueaert */ ...}
```

even when one employs `robot_uni_expr_add.semantics` instead of `robot.semantics`, one gets an error – this time, regarding the composition itself: “overriding object Left in trait syntax; object Left in trait syntax cannot override final member.” The problem here is with `robot_time` being an extension to `robot`, bringing the case object `Left` into the mix with that of `robot_uni_expr_add` that takes an argument.

B. Major Difficulties

The difficulties we spoke about in the previous subsection were not particularly acute in that not many circumvention attempts would fail for them. In this section, we will report a multi-staged combat with an acute difficulty we faced. In short, the combat was against the combination of Scala’s path-dependant typing and intervention of concrete syntax.

The contents of this section might look too specific to Scala. They are not. Scala’s path-dependant typing is just one way to foster family polymorphism [17] (as opposed to lightweight family polymorphism [18]). The familiar reader will figure out that the same problem is likely to emerge in every host language that embraces family polymorphism.

Given that `ExprMul` is a direct extension to `ExprAdd`, one’s first guess would be:

```
1 trait expr_mul.syntax extends expr_add.syntax {...}
```

That is, however, not possible because, then, Num cannot be overridden. Recall from Section II-E5 that ExprMul changes the syntactic category of Num. But, even an attempt like those in Section III-A1 for the syntax

```
1 trait syntax {
2   val easyn = new expr_add.syntax {} //expr_mul
3   import easyn.{Expr, Term, Add} /* Num, Factor, etc. */
4 }
```

would still cause failure for the semantics.

```
1 trait expr_mul.semantics extends syntax with
2   expr_add.semantics {...}
```

Here is the error message: “overriding object Num in trait syntax; object Num in trait syntax cannot override final member.” This is because of the clash between the Num of such a expr_mul.syntax and expr_add.semantics. See Section III-A2 for an explanation on similar error messages.

Now, let us suppose for the sake of argument that the semantics too selectively imports the ADT cases:

```
1 trait semantics { //expr_mul
2   val emsyn = new expr_mul.syntax {}
3   import emsyn.{Num, Mul, Factor}
4   val easyn = new expr_add.syntax {}
5   import easyn.{Expr, Add, Term}
6   ... /* value or value_ext here */ ...
7 }
```

Recall that ExprMul adds the ADT case Mul to ExprAdd. To reuse – à la LMS – the ExprAdd semantics whilst also handling the new ADT case, one may (mistakenly) try:

```
1 override def value: Expr => Int = {
2   case Mul(t, f) => value(t) * value(f) ...
3 }
```

But, that will not type-check because of path-dependant typing interference: Expr in value’s signature is different from Expr that Mul inherits from. Here is the error message for line 2 above: “constructor cannot be instantiated to expected type; found: semantics.this.emsyn.Mul required: semantics.this.Expr.” Even worse: An attempt for reusing the semantics of the only ADT case that remains intact over the move from ExprAdd to ExprMul using value_ext

```
1 trait semantics {... //expr_mul
2   import easem.{value_ext => add_value}
3   def value_ext: (Expr, Expr => Int) => Int = {
4     case (Num(n), c) => n
5     case (Add(e, t), c) => add_value(Add(e, t), c)
6     case (Mul(t, f), c) => c(t) * c(f) }
```

will again fail due to path-dependant typing. The error message for line 5 above is: “type mismatch; found: semantics.this.emsyn.Add required: semantics.this.easem.Expr.”

Given that expr_mul.semantics is to reuse pattern matching of expr_add.semantics, the former is also bound to the types – here, ADT cases – of the latter. In order to prevent the path-dependant clashes, thus, the only way forward seems to be for **both** expr_mul.syntax and expr_mul.semantics to import types of expr_add.semantics. This is, of course, very unnatural for the former.

```
value: Expr => Int
expr_add{Num, Add}, eaud{Num, Add, Var},
    expr_mul{Num, Add, Mul}
locate: Command => Unit (without e)
robot{Right, Left, Up, Down},
    robot_positive{Right, Up}
locate (with (e))
in reeaud: EnvComm => Unit
in robot_uni_expr_add: Commands => Unit
in rueaud: EnvComm => Unit
in robot_uni_expr_mul: Commands => Unit
EnvComm
reeaud, rueaud
```

Fig. 1: Duplicate Entities in Sections II and III

```
1 trait syntax { //expr_mul
2   val easem = new expr_add.semantics {}
3   import easem.{Expr, Term, Add}; ...
4   trait semantics extends syntax { //expr_mul
5     import easem.{Expr, Add, value_ext => add_value}
6     ...
7     def value_ext: (Expr, Expr => Int) => Int = {
8       case (Num(n), c) => n
9       case (a: Add, c) => add_value(a, c)
10    }
11    ...
12    ...
13 }
```

Still, if not done craftily enough, path-dependant typing can be an impediment. Replacing the line 9 above with

```
case (a @ Add(_, _), c) => add_value(a, c)
```

will fail to type-check because a is considered to be of type this.Add; whereas, add_value accepts an easem.Expr. The unsightly circumvention would be:

```
case (a @ Add(_, _), c) => add_value(a.
asInstanceOf[easem.Expr], c.asInstanceOf[easem.
Expr => Int]).
```

We would like to remind that all the difficulties illustrated in this section were only experienced in the presence of manipulation in the syntactic categories upon extension. Syntactic categories are often used for dealing with concrete syntax. Semantics, on the other hand, inputs abstract syntax. The following section presents a solution that disassociates concrete syntax from abstract syntax. It applies the LMS at the abstract syntax level, and, hence, independently of the concrete syntax that varies across languages. That design sets the different languages free on engineering their syntactic categorisation whilst enjoying the benefits of LMS.

IV. REFACTORING

The previous two sections were developed as if the guest language implementer was not aware in advance of the next guest languages and the upcoming combinations. We also maintained a backward compatibility policy in that we did not touch the older languages as we proceeded. Refactoring, however, is common in everyday software development.

Refactoring can have a variety of meanings, depending on the target and the methods used [19]. Here, we do not plan extensive refactoring. We only focus on duplicate elimination in the fashion of the *extract superclass* method [19, §12.6]. Fig. 1 lists a number of duplicates in Sections II–III.

We notice that the method `value` is duplicate in `expr_add`, `eaud`, and `expr_mul`. More precisely, the ADT cases `Num` and `Add` – which are, basically, inherited from `expr_add` – are handled thrice in the codebase. As will be shown in this section, we gave `value` its own abstraction.

We also notice that the method `locate` is present in two sets of language descriptions: in (i) `robot` and `robot_positive` (when the four direction commands do not take arguments); and, in (ii) `reeaud`, `robot_uni_expr_add`, `rueaud`, and `robot_uni_expr_mul` (when the four direction commands do take arguments). Each of those sets constitutes a candidate for refactoring. Finally, `EnvComm` is common between `reeaud` and `rueaert` – constituting yet another refactoring candidate. Although we have indeed refactored the candidates of this paragraph as well, we will not include their demonstration in this paper. The interested reader can look them up in our online codebase.

Let us now focus on refactoring the first row of Fig. 1. (Refactoring the other rows of Fig. 1 is done similarly.) Here is a succinct summary of actions to be taken: The idea is a combination of LMS and Component-Based Mechanisation [20], [21], [13]. We parameterise the ADT cases `Num`, `Add`, `Var`, and `Mul` by the language description and perform their semantics evaluation independently of the language description. We pack the two former cases – namely, `Num` and `Add` that are common between all the items in the first row of Fig. 1 – together in a trait. Then, we extend that trait for `Var` and later for `Mul`, both *à la* LMS. Finally, the concrete language descriptions only get to mix the respective abstract descriptions. The elaboration follows.

```
1 trait na_syntax {
2   type E //E for Expr
3   type N <: E //N for Num
4   type A <: E //A for Add
5
6   def n_extr(n: N): Option[Int]
7   def a_extr(a: A): Option[(E, E)]
8
9   object N {def unapply(n: N) = n_extr(n)}
10  object A {def unapply(a: A) = a_extr(a)}
11 }
12 trait na_semantics extends na_syntax {
13   def value: E => Int = {
14     case N(n) => n
15     case A(e1, e2) => value(e1) + value(e2)
16   }
17 }
```

In the trait `na_syntax` above, the abstract type `E` (in line 2) is a language-independent representation for the expression type of a guest language. Such a guest language can be an item in row 1 of Fig. 1 or any similar language with integer arithmetics that at least contains integral literals and addition. Given that ADTs are implemented in Scala using plain inheritance, two more language-independent abstract types have been employed that are announced to be extending `E`. Those are `N` for `Num` and `A` for `Add`, in lines 3 and 4.

Because `N` and `A` are supposed to later be instantiated to the respective cases of an ADT, they are expected to come with the Scala matching syntax, like those in lines 14 and 15. The Scala machinery for enforcing availability of the desirable matching syntax requires a discipline in coding that

is slightly tricky. The discipline involves, for each ADT case abstract type, inclusion of a same-named (singleton) object – called *companion* object – that ships, then, with an *extractor*, i.e., an *unapply* method of the right type signature. The actual duty of the extractor is relayed to an abstract method, to be enforced to every guest language that implements `na_syntax`. For `N`, for instance, that duty is on `n_extr` in line 6. The Scala signature of `n_extr` means that, if matching `N` succeeds, it would be initialising an argument of type `Int`. All that wiring enables the method `na_semantics.value` to handle the semantics of `Num` and `Add`.

```
1 trait nam_syntax extends na_syntax {
2   type M <: E
3   def m_extr(m: M): Option[(E, E)]
4   object M {def unapply(m: M) = m_extr(m)}
5 }
6 trait nam_semantics extends nam_syntax with na_semantics {
7   override def value: E => Int = {
8     case M(e1, e2) => value(e1) * value(e2)
9     case e => super.value(e)
10  }
11 }
```

The trait `nam_syntax` adds the abstract type `M` (in line 2 above), which corresponds to `Mul`. It also provides the Scala matching syntax in lines 3 and 4. The trait `nam_semantics` reuses (*à la* LMS) what is already implemented by `na_semantics` by performing a *super* call on the relevant ADT cases (line 9).

```
1 trait expr_add.syntax extends na_syntax {
2   /* ... like lines 2 to 10 of
3     expr_add.syntax in Section II ... */
4   type E = Expr //Fix the ADT type.
5   type N = Num //Fix the Num case.
6   type A = Add //Fix the Add case.
7   //And, fix the extractors.
8   def n_extr(n: Num) = Num.unapply(n)
9   def a_extr(a: Add) = Add.unapply(a)
10 }
11 trait expr_add.semantics extends
12   expr_add.syntax with na_semantics
```

In addition to working out the Section II concrete syntax, the trait `expr_add.syntax` above, now is required to provide evidence on it indeed having ADT cases for integral literals and addition. That, again involves some slightly tricky discipline consisting of two steps. First, in lines 4 to 6, the concrete counterparts for the abstract (ADT case) types in `na_syntax` are fixed. Second, in lines 8 and 9 the extractors promised to `na_syntax` are fixed.

Recall from `expr_add.syntax` of Section II that `Num` and `Add` are both case classes. Scala actually desugars case classes to normal classes in addition to companion objects with the right-typed *unapply* methods. That is why we can use `Num.unapply` and `Add.unapply` off-the-shelf.

Nothing more remains for `expr_add.semantics` to do except inheriting its (abstract and concrete) syntax from `expr_add.syntax` and its semantics from `na_semantics`.

```
1 trait expr_mul.syntax extends nam_syntax {
2   val easyn = new expr_add.syntax {}
3   import easyn.{Expr, Term, Add};...
4   //like lines 4 to 11 of expr_mul.syntax in Section II...
5   type E = Expr; type N = Num; type A = Add; type M = Mul
6   def n_extr(n: Num) = Num.unapply(n)
7   def a_extr(a: Add) = Add.unapply(a)
8   def m_extr(m: Mul) = Mul.unapply(m) }
```

```

9 trait ExprMulSemantics extends
10   ExprMulSyntax with NamSemantics

```

Implementing `ExprMul`, in this fashion, is similar, as demonstrated above. It only is that, like in Section III, our use of traits instead of objects in favour of LMS imposes instantiation of the trait `ExprAddSyntax` (line 2) before `importing` the desirable concrete syntax items (line 3).

Remarks

`na_semantics` is similar to how one defines the semantics of `Num` and `Int` using Modular Structural Operational Semantics (MSOS) [22]. In MSOS, the semantics of a component is defined exclusively in terms of the relevant language elements – making it ignorant about all other language elements. `na_semantics` only concerns `Num` and `Int`, and, is ignorant about other language elements. $\gamma\Phi C_0$ [13] describes that as: “client $na_semantics \langle F \triangleleft Int \oplus Num \rangle \{ \dots \}$,” where F is the *family parameter* of $na_semantics$. In words, that reads: A family Φ to be substituted for F needs at least to have components *Int* and *Num* (or their equivalents) in its mix.

From another language theoretical viewpoint, `na_syntax` and `na_semantics` are both type classes [23]. From that viewpoint, `ExprAddSyntax` is an instance of `na_syntax` and `ExprAddSemantics` is an instance of `na_semantics`. The evidence for the former is provided in lines 2 to 7 in `na_syntax`. Interestingly, however, our encoding of type classes in Scala is not the common one [24]. In particular, we do not prescribe the use of `implicit`s.

As also announced at the last paragraph of Section III, `na_syntax` and `na_semantics` (and also `nam_syntax` and `nam_semantics`) relate to the abstract syntax only. This is how they leverage LMS and yet do not suffer from the concrete syntactic anomalies discussed in Section III. Moreover, unlike Modular Reifiable Matching [25], the technique we presented in this section is not exclusively targeting two-level types [26]. The reason is that our technique in this section fully disassociates concrete syntax from the abstract syntax so there no longer is an issue of levels in the types. LMS itself comes with no such separation either – suggesting the name *abstract LMS* for our technique.

It is noteworthy that the disassociation of abstract and concrete syntax with the lack of the LMS anomalies discussed in Section III needs not specifically be *à la* LMS. The same impact can also be achieved using integration of a decentralised pattern matching [27]. In the latter technique, the syntax is defined in terms of abstract syntax components. The concrete syntax in the latter technique is then defined on top of those syntax components. The difference is that the abstract LMS composes components (that correspond to ADT cases) *additively* [28, §17.3], whilst the latter technique would be composing them *sequentially*.

The connection between this technique and Component-Based Software Engineering (CBSE) [28, §17],[29, §10] is also interesting. From a CBSE standpoint, `nam_syntax` is a component in that: Without binding to a particular implementation, it specifies its so-called ‘requires’ and ‘provides’

interfaces. The `nam_syntax` ‘requires’ interface is its lines 2 and 3 – imposing the following two requirements, respectively: The user of `nam_syntax` needs to provide a type `M`. And, there has to be a way to extract two expressions of type `E` from an instance of `M`. In return, the ‘provides’ interface of `M` is its line 4, where `M`’s Scala match syntax (used in line 8 of `nam_semantics`) is offered. As such, `nam_syntax` is promoting the ADT case `Mul` to its standalone component.¹ This is an important characteristic of the third technique that relates to the EP. Next section is dedicated to that relationship.

V. EXPRESSION PROBLEM

EP is a recurrent problem in the field of Programming Languages, for which a wide range of solutions have thus far been proposed, e.g., [31], [32], [33]. Consider [34], [35], [36], [31], [32], [33], to name a few. Haeri [21] defines EP as the challenge of finding an implementation for an ADT – defined by its cases and the functions on it – that:

- E1. is *extensible in both dimensions*, i.e., both new cases and functions can be added.
- E2. provides *weak static type safety*, i.e., applying a function f on a statically² constructed ADT term t should fail to compile when f does not cover all the cases in t .
- E3. upon extension, forces *no manipulation or duplication* to the existing code.
- E4. accommodates *separate compilation*, i.e., compiling the extension imposes no requirement for repeating compilation or type checking of existing code. Such static checks should not be deferred to the link or run time.

In Sections II–IV, we presented three techniques for embedded language composition in Scala. All the three techniques satisfy E4. We now reflect on their E1–E3 competence: The first technique clearly satisfies E1. Section III-A2 outlines a scenario where LMS fails to satisfy E1. Whether the third technique satisfies E1 depends on whether it employs trait mixing for composition or not. Note that it needs not. The three techniques all relax E2, although they can be circumvented to work when defaults are available [35]. That is a consequence of Scala performing pattern matching at runtime. LMS too relaxes E2 and that has thus far been considered an acceptable setting. (For example, MVCs [37] and Torgersen’s second solution [34] both have the same issue.) The state of affairs for LMS might change in future though [38].

As witnessed by `RobotUniExprAddUniDec` in Section II-E1, the Scala-unspecific technique fails to satisfy E3 when new cases are to be added. As detailed in Section III-B, LMS has to fight path-dependant typing to satisfy E3 when syntactic categories are updated upon composition. Whether there always is a winning strategy for LMS in such a situation is not known. The third technique clearly satisfies E3.

¹Two reasons for not promoting `Num` and `Add` to components: 1) that would complicate presentation. 2) the current design in which those two ADT cases are packed together in a single component (i.e., `na_syntax`) demonstrates how to address the Common Reuse Principle of Martin [30].

²If the guarantee was for dynamically constructed terms too, we would have called it strong static type safety.

We understand that the path-dependant typing difficulties of the LMS-based technique might indeed be a result of our peculiar design. In particular, our choice of giving the syntax and semantics of a language each a trait of their own might be picked as the root cause. We would like to defend that choice of ours, specifically, for the likelihood of engineering (or experimentation with) more than one semantics for the same syntax [15]. In such cases, separation of the syntax and semantics is inevitable.

Finally, one may wonder whether the third technique makes it to a new solution to EP. The answer is indeed yes. At least for EP in presence of defaults [35]. This is the third EP solution of its kind: It promotes ADT cases to their own ADT-parameterised components. See [20], [21] for the first and [27] for the second EP solution of this kind.

VI. RELATED WORK

a) *LISA*: As stated earlier, this paper is highly inspired by Mernik [6]. We essentially took his examples for showing how to compose languages embedded in Scala. With LISA being an LDF, even though Scala is famous for its hospitality to embedded languages, we were surprised to end up having less lines-of-code (LoC) in all the three techniques.

Fig. 2 summarises the LoC comparison. In the LoC there, we have also included some syntactic cosmetics that we did not display in this paper. In our experience, the occasions where Scala outperforms LISA by far are those where the task was a ready cake for GPLs. Examples are `RobotTime` for all the techniques and `RobotExtExprAddUniDec` for the third technique. For the former, a simple container size query does the job. For the latter, simple trait mixing does.

The first technique generally performs better (in terms of LoC) than LISA. The second is even better usually with its utilisation of trait mixing (dismissing the obvious `import s`) and `super` calls. At last, the third is the best with its a posteriori refactoring. The two occasions when LISA considerably outperforms Scala are `RobotUniExprAdd` for the first technique and `RobotUniExprMul` for the third. Those correspond to Sections III-A2 and III-B, respectively.

The factored out code in the third technique is not counted in Fig. 2. Once that too is added, the total LoC reaches 328 – which is 2 more than first technique’s LoC. We tend to think the reason is the simplicity in the semantics of Mernik’s examples. That caused the number of lines the refactoring saves to be less than the extra overhead the technique requires. For more realistic case studies, we expect the balance to be completely different. That would be well in favour of refactoring due to reasonably more involved semantics.

b) *Other Language Composition Catalogues*: Völter [39] proposes a taxonomy of language composition that he showcases in *JetBrains MPS*. His taxonomy is along axes, not all of which having a clear correspondent in the work of Erdweg et al. As explained by Mernik, the resulting ways for language composition that Völter prescribes, however, are subsumed by the latter taxonomy. Völter’s taxonomy gives (syntax-oriented) IDE development for languages a higher weight.

Barrett, Bolz, and Tratt [40] catalogue composition of six different Python and Prolog virtual machines. Their study has a particular focus on measuring performance of the resulting interpreters upon composition.

Zhang et al. [41] facilitate composition of languages that are embedded using Object Algebras [42]. This is achieved using their simple predesignated annotation. Their showcase focuses on hierarchies of language extension. Using linearised multiple language inheritance, they also simulate a single language unification. Zhang et al. do not consider higher order composition.

Melange [43] is an LDF that is specially equipped for language composition. Various syntactic facilities are available in Melange to instruct mix-and-match for many different aspects of a language – ranging from syntax, dynamic and static semantics, and name-binding to IDE features. Language composition under Melange is catalogued for a small set of showcases but with in-length discussions on customisability. The current documentation of Melange, however, makes it hard for us to compare its catalogue of language composition with similar works. Specifically, we fail to figure out which ways for language composition Melange supports in general (namely, for other scenarios than the ones already in their documentation) and how.

c) *Components for Language Specification*: *PLanCompS* funcons are syntactic constructs that ship with their own fixed static and dynamic semantics (presented in MSOS). The *PLanCompS* specification of a programming language is developed by merely assembling funcons [44]. Example assemblies are larger academic languages [45] and medium-scale ones [46]. Despite their merit, funcons do not constitute CBSE components. In particular, funcons do not ship with their ‘requires’ interfaces.

MVCs [37] are components for solving an extension to EP. Rather than components in their CBSE sense, however, MVCs are components in a Component-Oriented Programming [47] sense. (Cf. [21, §4.3].) MVCs rely on the implementation details of *how* a component realises its interfaces. CBSE components, in contrast, are identified by their ‘requires’ and ‘provides’ interfaces.

Haeri and Schupp [20], [27] take a CBSE approach for the implementation of embedded languages. Their approach employs type constraints and multiple inheritance. The third technique here employs (possibly constrained) abstract types instead of type parameters. Although essentially the same, the former can make code terser. In Scala, however, offering the match syntax is apparently not possible for type parameters.

Finally, Cazzola and Vacchi [48] too have taken a CBSE approach. Their components correspond to a DSL’s compiler passes. Accordingly, how their work relates to the common language specification formalisms is not clear. In contrast, components in our third technique are ADT cases – acting as the unit of study for formal semantics.

d) *Component-Based AGs*: AGs are a powerful means for language specification with many benefits that are well-studied. Attempts to modularise AGs go back to Saraiva and

	L_1	L_2	L_3	L_4	L_5	L_6	L_7	L_8	L_9	L_{10}	L_{11}	L_{12}	L_{13}	Sum
LISA	42	23	13	19	19	32	39	41	20	34	23	20	19	344
T_1	32	7	16	26	34	11	40	25	31	34	17	22	31	326
T_2	30	6	15	20	29	10	34	20	26	28	13	23	33	287
T_3	29	5	15	16	16	10	10	20	23	6	13	23	16	202

Columns: L_1 = Robot, L_2 = RobotTime, L_3 = RobotPositive, L_4 = ExprAdd, L_5 = RobotUniExprAdd, L_6 = Dec, L_7 = RobotUniExprAddUniDec, L_8 = RobotTimeSpeed, L_9 = ExprAddUniDec, L_{10} = RobotExtExprAddUniDec, L_{11} = RobotUniExprAddExtRobotTime, L_{12} = ExprMul, L_{13} = RobotUniExprMul Rows: LISA = Mernik's Implementation, T_i = Technique i , for $i \in \{1, 2, 3\}$

Fig. 2: Lines-of-Code Comparison between Mernik's LISA and Our Three Techniques

Swierstra [49]. Saraiva's Higher Order AGs (HOAGs) [50] were the initial steps towards using AGs in a component-based fashion. Viera and Swierstra [51] formally define several ways to combine HOAGs. However, those ways do not tightly correspond to the usual composition mechanics of general-purpose languages.

So long as EP is concerned, the correct behaviour of a HOAG w.r.t. E2 is not universally agreed upon. In terms of HOAGs, that amounts to the absence of an attribute expected from another component in the mix. In particular, should the code then fail statically or dynamically? Zipper functions [52], [53] act like HASKELL by statically reporting such errors so long as they can be caught iteratively [54].

Kiama [55] uses AGs embedded in Scala for language specification. It is possible to use Kiama in a component-based fashion – as done for embedding Oberon-0 [56] in Scala [57]. However, disassociation of the concrete and abstract syntax can become non-trivial in Kiama. We anticipate that would cause similar difficulties to those we faced over our second technique. For the Oberon-0 embedding, facing such difficulties were unlikely for the different pieces of syntax were all available in advance. On the contrary, whilst composing unrelated pieces of syntax, clash of concrete syntax is likely.

VII. CONCLUSIONS AND FUTURE WORK

In this paper we present three different techniques for composing languages embedded in Scala. The first is Scala-unspecific and works in presence of common module systems and higher order functions (Section II). The second is LMS-based and requires mixin composition and `super` calls (Section III). The third works by promoting ADT cases to ADT-parameterised components (Section IV). We showcase the three techniques using the example compositions of Mernik, which, in return, were designed to exhibit LISA's composition facilities for Erdweg et al.'s taxonomy of composition. We manifest the strengths and weaknesses of each technique. We compare them according to their performance as EP solutions (Section V) and LoC (Section VI-0a).

Systematic study of embedded language composition is a young topic. Numerous paths exist for future research. Examining our third technique against larger testcases is an immediate future work. A promising candidate is the [LDTA'11 challenge](#) of modular implementation of Oberon-0. The testcase can then be compared with the LDTA'11 contestants. We anticipate complications in dealing with a few

issues along the way: Firstly, the technique takes a design-by-contract approach on the names it chooses for abstract types, e.g., `A` and `N` in `na_syntax`. In large scale, these names are likely to clash upon composition. Avoiding that would imply a priori knowledge. That kind of knowledge is, however, rare in experimental language design. Secondly, outside lab settings, usual software engineering techniques may become inevitable. We took the lab liberty of not being concerned with that here. For example, `position` and `consts` lack proper scoping and are common intact amongst all the descendants of `Robot` and `Dec`, respectively.

Type classes are more widely practised in HASKELL. It would be interesting to see our third technique in HASKELL with its type classes instead of Scala's mixins and inheritance. The comparison between the results of ours and those according to the following two HASKELL EP solutions would be particularly interesting: Data Types a la Carte [36] and Parametric Compositional Datatypes [32].

Object Algebras are gaining gravity as a powerful abstraction for embedded language development [31], [58], [59], [41]. The current technology for embedding Object Algebras, however, is heavyweight in both term creation [60] and algebra composition. It is easy to turn `na_syntax` and the like into Object Algebra Interfaces to lower those two weights. How useful the result would be in lowering those two weights in the current Object Algebras technology is another future work.

Finally, it is important to also produce catalogues like this paper in other host languages than Scala. Many languages have merits in hosting other languages. But, the limits of that and the key factors of it are not clear. Composition of the embedded languages is certainly amongst the important factors. A head-to-head comparison on hospitality of language composition is missing. We are currently working on that.
